Among the known options in carbon capture and storage, the injection and storage of carbon dioxide (CO$_2$) in deep saline aquifers has the potential to cause casing corrosion due to the direct contact between injected CO$_2$ and the saline aquifer, which contains highly concentrated aqueous salts such as sodium chloride (NaCl) and calcium chloride (CaCl$_2$). Thus, in the present study, the effect of Ca$^{2+}$ on the CO$_2$ corrosion behavior of mild steel was investigated in simulated saline aquifer environments. The results show that with low concentrations of Ca$^{2+}$, the corrosion rate decreased with time due to the formation of protective iron carbonate (FeCO$_3$) and/or Fe$_x$Ca$_y$CO$_3$ ($x + y = 1$). The presence of high concentrations of Ca$^{2+}$ lead to an increasing corrosion rate with time.

**Effect of Calcium on the Formation and Protectiveness of an Iron Carbonate Layer in CO$_2$ Corrosion**

Saba Navabzadeh Esmaeely, Yoon-Seok Choi, David Young, and Srdjan Nešić, FNACE, Institute for Corrosion and Multiphase Technology, Ohio University, Athens, Ohio

Since carbon dioxide (CO$_2$) emission is directly proportional to fossil fuel consumption, the capturing and subsequent geologic storage of CO$_2$ is a candidate technology for controlling its emission. The carbon capture and storage (CCS) process contains three stages: CO$_2$ capture, transportation to the geologic storage site (usually by pipeline), followed by injection into geologic reservoirs.

Corrosion rates of casing steel are highly dependent on the formation of iron carbonate (FeCO$_3$) in CO$_2$/saline aquifer environments. Brine species such as Ca$^{2+}$, which can form carbonate layers/scales, are very important in corrosion studies as they can compete with Fe$^{2+}$ in the formation of carbonates. Therefore, there is a possibility of changing the FeCO$_3$ morphology, composition, and protectiveness in such environments, which can in turn affect general and localized corrosion of casing steel.

Little has been reported in the literature on the effect of Ca$^{2+}$ on corrosion. Xian, et al. claimed that corrosion rate decreased in the short term in the presence of Ca$^{2+}$ and Mg$^{2+}$, but there was no special difference in long-term exposure. Ding, et al. reported the corrosion rate increased with an increase in the Ca$^{2+}$ concentration. Jiang, et al. reported pitting associated with calcium chloride (CaCl$_2$). They claimed that Cl$^-$ caused pitting, but the presence of Ca$^{2+}$ postponed the initiation of the pitting. Ren, et al., as well as Zhu, et al., reported pitting with reference to the presence of Cl$^-$ in CaCl$_2$-containing electrolytes. Gao, et al. reported pitting in conjunction with the formation of Fe$_x$Ca$_y$CO$_3$ and Fe$_x$(Mg, Ca)$_y$CO$_3$ ($x + y = 1$) on the steel surface. A broader review of the literature indicates that Cl$^-$ ions are often associated with pitting. The role of overall water chemistry, and Ca$^{2+}$ ions in particular, is generally not clear.
The objective of the present study is to evaluate the effect of Ca\textsuperscript{2+} on the CO\textsubscript{2} corrosion behavior of mild steel in simulated saline aquifer environments related to the injection and storage of CO\textsubscript{2} by conducting well-controlled and thoroughly qualified experiments.

**Experimental Setup and Procedure**

Experiments were conducted in a 2-L glass cell using a three-electrode setup. In each experiment, three flat specimens made from mild steel (UNS G10180) with an exposed area of 540 mm\textsuperscript{2} were used for electrochemical measurement and for surface analysis. Prior to insertion, the specimens were wet-polished with silicon carbide (SiC) paper down to 600 grit, rinsed with isopropyl alcohol in an ultrasonic bath, and dried.

Tables 1 and 2 show the test matrix and test conditions, respectively. The glass cell was filled with 2 L of 1 wt\% sodium chloride (NaCl) electrolyte (prepared with deionized water). The solution was stirred with a magnetic stirrer and the temperature was set to 80 °C. CO\textsubscript{2} gas was continuously purged through the solution. The solution pH was adjusted to 6.6 by adding a deoxygenated 1.0 M sodium hydroxide (NaOH) solution. After the pH stabilized, the magnetic stir bar was stopped and samples were inserted into the glass cell.

The corrosion behavior was monitored by electrochemical methods: open circuit potential (OCP) and linear polarization resistance (LPR) measurements. Samples from all experiments were characterized by x-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive x-ray spectroscopy (EDS), and infinite focus microscopy (IFM) to investigate the effect of Ca\textsuperscript{2+} on the morphology and composition of the corrosion product layer. The Ca\textsuperscript{2+} concentration was measured using inductively coupled plasma (ICP) spectroscopy. Analyses for the Fe\textsuperscript{2+} concentration were performed with an ultraviolet-visible (UV-Vis) spectrophotometer.

At the end of each experiment and after completion of the corrosion product surface analysis, one sample from each experiment was treated with Clarke solution to remove the corrosion product layer and the underlying metal surface, was scanned in accordance with ASTM G1.\textsuperscript{10}

**Results**

Figure 1 shows the variations of OCP and corrosion rate with time for each experiment condition. As shown in Figure 1(a), the corrosion rate decreased with time for the low initial Ca\textsuperscript{2+} concentration conditions. This indicates that a protective FeCO\textsubscript{3} layer was formed on the steel surface.

When a FeCO\textsubscript{3} layer forms on the mild steel surface, it can slow down corrosion by presenting a diffusion barrier for the species involved in the process, and by blocking (covering) a portion of the steel surface and preventing the underlying steel from undergoing further oxidative dissolution.\textsuperscript{11,12}

For the low initial Ca\textsuperscript{2+} concentration conditions (0, 10, and 100 ppm), the formation of a protective FeCO\textsubscript{3} layer apparently occurred without significant interference.

**FIGURE 1** Variations of (a) corrosion rate and (b) OCP for mild steel exposed to a simulated brine with different initial concentrations of Ca\textsuperscript{2+} at 80 °C and pCO\textsubscript{2} of 0.05 MPa with 10 ppm Fe\textsuperscript{2+}.  

NACE INTERNATIONAL: VOL. 53, NO. 5  MATERIALS PERFORMANCE MAY 2014
by Ca\(^{2+}\) ions. However, the corrosion behavior of mild steel with higher initial Ca\(^{2+}\) concentrations of 1,000 and 10,000 ppm was different. The corrosion rate did not decrease with time, which is likely due to the lack of formation of a protective FeCO\(_3\) layer on the steel surface. At this stage, it can be hypothesized that this was caused by a lower pH seen in experiments with higher initial Ca\(^{2+}\) concentrations. Precipitation of calcium carbonate (CaCO\(_3\)) in aqueous CO\(_2\) solutions will lead to acidification as the equilibrium pH is approached.

The experiments with lower Ca\(^{2+}\) concentrations remained highly supersaturated with respect to FeCO\(_3\) during the whole experiment, leading to steady precipitation of protective FeCO\(_3\). The experiment with initial Ca\(^{2+}\) concentration of 1,000 ppm also was supersaturated with respect to FeCO\(_3\). At the initial Ca\(^{2+}\) concentration of 10,000 ppm, the rapid precipitation of CaCO\(_3\) made the solution undersaturated with respect to FeCO\(_3\), making

**FIGURE 2** (a) Fe\(^{2+}\) and Ca\(^{2+}\) concentrations and (b) CaCO\(_3\) and FeCO\(_3\) saturation degree for the initial 1,000 ppm Ca\(^{2+}\) system vs. time at 80 °C and pCO\(_2\) of 0.05 MPa with 10 ppm Fe\(^{2+}\).

![Figure 3](image2.png)

**FIGURE 3** SEM images of recovered samples (UNS G10180) from experiments conducted at 80 °C and pCO\(_2\) of 0.05 MPa with 10 ppm Fe\(^{2+}\) for (a) 0 ppm Ca\(^{2+}\), (b) 10 ppm Ca\(^{2+}\), (c) 100 ppm Ca\(^{2+}\), (d) 1,000 ppm Ca\(^{2+}\), and (e) 10,000 ppm Ca\(^{2+}\).
it impossible for a protective FeCO₃ layer to form.

Focusing on the experiment with initial Ca²⁺ concentration of 1,000 ppm will explain this behavior in more detail. The measured variations of Fe²⁺ concentration and Ca²⁺ concentration with time are plotted in Figure 2(a). The concentration of Ca²⁺ decreased steadily due to precipitation of CaCO₃. The Fe²⁺ concentration initially decreased due to precipitation of FeCO₃ from a supersaturated solution. Then, as the saturation level was approached, the Fe²⁺ concentration increased due to the high general corrosion rate (Figure 1[a]). The corresponding saturation degrees with respect to CaCO₃ and FeCO₃ vs. time are given in Figure 2(b). There, based on the measured pH and Ca²⁺, the saturation degree with respect to CaCO₃ was calculated.

As is shown in Figure 2, because of a very high initial concentration of Ca²⁺, the aqueous solution was initially highly supersaturated with respect to CaCO₃. This led to precipitation of CaCO₃, reducing the level of saturation. As the CaCO₃ supersaturation level approached 10, the driving force for CaCO₃ precipitation decreased and the concentration of calcium changed very slowly. At the same time, the Fe²⁺ concentration initially decreased much more rapidly than the Ca²⁺ concentration even if the initial level of supersaturation with respect to FeCO₃ was much lower than that of CaCO₃, which points to much faster kinetics. As the level of FeCO₃ supersaturation fell below 10, the kinetics of FeCO₃ precipitation decreased. At the same time, the corrosion rate remained unchanged (Figure 1[a]), which led to an increase in Fe²⁺ concentration over time.

Figure 3 shows SEM images of specimens from electrolytes with 0 ppm Ca²⁺, 10 ppm Ca²⁺, 100 ppm Ca²⁺, 1,000 ppm Ca²⁺, and 10,000 ppm Ca²⁺. The analyses for the
experiments with 0, 10, and 100 ppm Ca\textsuperscript{2+} (Figures 3[a], [b], and [c]) show scattered crystals of FeCO\textsubscript{3} on the surface. Corrosion product crystal morphologies did not appreciably change at these relatively low Ca\textsuperscript{2+} concentrations. However, at higher Ca\textsuperscript{2+} concentration, as shown in Figures 3(d) and (e) for 1,000 ppm Ca\textsuperscript{2+} and 10,000 ppm Ca\textsuperscript{2+}, respectively, the crystal morphologies at the surface significantly changed due to the presence of Ca\textsuperscript{2+}. In the experiment with 1,000 ppm Ca\textsuperscript{2+}, the crystals were mostly elongated. For the electrolyte with 10,000 ppm Ca\textsuperscript{2+}, the surface was covered with a dense, intergrown layer of scale rather than being comprised of relatively discrete crystals.

The XRD data of specimens tested with 0 ppm Ca\textsuperscript{2+} and 10 ppm Ca\textsuperscript{2+} confirmed the presence of FeCO\textsubscript{3} on the surface. It can be concluded from XRD data on the specimen tested with 10 ppm Ca\textsuperscript{2+} that a thick and protective layer was formed on the surface, as the main peak of α-Fe related to diffraction from the steel substrate cannot be detected. The XRD data show less intense, broadened, and shifted peaks as a result of the substitution of the larger Ca\textsuperscript{2+} for Fe\textsuperscript{2+} in the FeCO\textsubscript{3} structure. This causes the formation of a solid solution with the formula Fe\textsubscript{x}Ca\textsubscript{y}CO\textsubscript{3}, (x + y = 1).

Similar to the experiment condition no. 2 with the addition of 10 ppm Ca\textsuperscript{2+}, the XRD data for the specimen tested with 100 ppm Ca\textsuperscript{2+} again show broadened and shifted peaks relative to FeCO\textsubscript{3} with their more profound differences, compared with 10 ppm Ca\textsuperscript{2+} due to the higher concentration of Ca\textsuperscript{2+} in the electrolyte. This is a consequence of greater substitution of Fe\textsuperscript{2+} with Ca\textsuperscript{2+} during formation of the solid solution; compositional complexity and concentration gradients within the Fe\textsubscript{x}Ca\textsubscript{y}CO\textsubscript{3} scale are reflected by significant asymmetry in the principle diffraction peaks between 30-32°.

The XRD data for the specimen tested in 1,000 ppm Ca\textsuperscript{2+} are indicative of a transition to a physical mixture of CaCO\textsubscript{3} with a solid solution of Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7} on the steel surface. The high corrosion rate in this experiment may be the result of the formation of mostly Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7} rather than FeCO\textsubscript{3} or Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7} on the surface. This would indicate that CaCO\textsubscript{3} is not as protective as FeCO\textsubscript{3} or Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7}. According to the XRD data for the specimen tested with 10,000 ppm Ca\textsuperscript{2+}, there is a physical mixture of the CaCO\textsubscript{3} and a solid solution of Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7} on the surface. The high corrosion rate in this experiment is likely the result of the formation of mostly Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7} with a high concentration of Ca\textsuperscript{2+} on the steel surface.

Figures 4(a) and (b) show the cross section analysis of the tested conditions with 1,000 and 10,000 ppm Ca\textsuperscript{2+}. There is not a significant difference in the layer on the surface between 0 and 10 ppm Ca\textsuperscript{2+}. On the other hand, in the presence of 1,000 ppm Ca\textsuperscript{2+} (Figure 4[a]), two different layers on the steel surface were detected. The concentration of Fe in the layer immediately adjacent to the steel surface is higher than Ca\textsuperscript{2+}, whereas the layer on the outer surface has the opposite relationship. Taken in conjunction with the cross section analysis, this would imply that a bilayer structure had formed with CaCO\textsubscript{3} scale growing from the surface of the Fe\textsubscript{2}Ca\textsubscript{3}CO\textsubscript{7} corrosion product. Figure 4(b), the cross section analysis of the experiment with 10,000 ppm Ca\textsuperscript{2+}, does not show an obvious bilayer structure at the steel surface. There is, however, a significant Ca/Fe concentration gradient consistent with the XRD data. There seems to be an increased “roughening” of the steel surface as the Ca\textsuperscript{2+} concentration increases.

SEM images of the surface were obtained after specimens were treated with Clarke solution, which completely removed the surface layer. General roughening of the surface is confirmed as the Ca\textsuperscript{2+} concentration is increased. At the highest Ca\textsuperscript{2+} concentration of 10,000 ppm, there appears to be some initiation of pitting, but this is difficult to judge because of the relatively short duration of the experiments. The calculated maximum penetration rate, according to the deepest pit found by IFM analysis, is 6.0 mm/yr, as shown in Figure 5. This is significantly higher than the average uniform corrosion rate detected by LPR (Figure 1[a]).

Conclusions

- The presence of Ca\textsuperscript{2+} affected the corrosion behavior by changing the water chemistry, particularly as the formation of nonprotective CaCO\textsubscript{3} interfered with the formation of protective FeCO\textsubscript{3}.
- The low Ca\textsuperscript{2+} concentration (<100 ppm) did not significantly affect the corrosion rate.
• At a high concentration of Ca²⁺ (≥1,000 ppm), the corrosion behavior was different and high corrosion rates were observed.
